

Ina Lunar Irregular Mare Patch (IMP) **Mission Concepts: Distinguishing  
Between Ancient and Modern Volcanism Models**

Le Qiao<sup>1,2</sup>, James W. Head<sup>3</sup>, Lionel Wilson<sup>4</sup>, and Zongcheng Ling<sup>2</sup>

Abstract

The Ina Irregular Mare Patch (IMP), a  $\sim 2 \times 3$  km summit depression on an ancient  $\sim 22$  km diameter shield volcano, displays two very enigmatic units: 1) dozens of dark convex-upward mounds, 2) a very rough, optically immature floor unit, with very sharp morphologic contacts between the two. Controversy surrounds the age interpretation of Ina: superposed impact crater size-frequency distributions (CSFD) suggest an age of  $\sim 33$  Ma, consistent with the presence of sharp contacts between the units, and indicating that mare volcanism continues to today. Models of the terminal stages of volcano summit pit crater activity suggest an age coincident with the building of the shield,  $\sim 3.5$  Ga; these models interpret the CSFD age and sharp contacts to be due to an extremely porous lava lake floor, and extrusion and solidification of magmatic foams. We present robotic-human exploration mission concepts designed to resolve this critical issue for lunar thermal evolution.

## 1. Introduction and Background

While examining the high-resolution orbital photographs taken by the Apollo 15 crew in August 1971, Whitaker (1972) noted a very unusual and enigmatic depression feature (**18.66°N, 5.30°E**), ~3 × 2 km in size, with about half of the depression floor covered with blobs of mare materials with an appearance similar to "dirty mercury." Located in a small mare in the central portion of the nearside Moon, the feature was informally named "D-Caldera" (Cernan et al. 1972; El-Baz 1973; Evans & El-Baz 1973) and then formally known as Ina (Defense Mapping Agency 1974; Strain & El-Baz 1980) (Figures 1 and 2). Its peculiar shape and interior structures intrigued many Apollo program scientists (El-Baz 1972, 1973; Whitaker 1972). Soon after its discovery, a special orbital visual observation effort for the Ina feature was planned during the Apollo 17 mission in December 1972. The Command Module Pilot (CMP) Ronald E. Evans then presented remarkable observations of the Ina/D-Caldera feature from lunar orbit (Cernan et al. 1972):

"[The] D-Caldera is sure a depression. Like nothing I've ever seen before ... At this point, you get a dark tan, a mare-type material. And then it is a light gray down in the D-Caldera itself ... And then it has got bumps that stick up, and the bumps themselves are the light tan material... And down between the bumps [is] a rough, blocky, gray material." (CMP, revolution 28; words in brackets are not original)

"The pictures confirm a topographic rise around the D-Caldera, just a slight one, and it is about half the width of the D-[Caldera]. And it seems to be a raised, flat rim around it. The color of the raised bumps down in the D-Caldera are the same as the surrounding material. The bumps that are raised up are smooth looking and ... the part of the depression, anyhow, is a light bluish gray." (CMP, revolution 36)

"Down in the caldera, the gray blocky-type of stuff [looks like] water drops on a surface ... But it would leave a depression due to a surface tension ... And then you have little bubbles that float across there ... I could not see a light-colored annulus [around D-Caldera] ... There is nothing surrounding D-Caldera that looks like the silver, gray material that has depressed. The little bumps in D-Caldera are the same color and the same smoothness as the mare material surrounding the area." (CMD, revolution 40)

In addition, the Apollo 17 mission also obtained a sequence of orbital photographs with both color and black-white film. Many Apollo 17 photographs were taken at very low-Sun illumination conditions, which exaggerated surface object shadow patterns and thus significantly enhanced surface morphologic detectability. Geological investigations of these photographs identified Ina

as a summit vent depression atop a small extrusive lava dome, with a raised rim "collar" feature (El-Baz 1973; Evans & El-Baz 1973; Strain & El-Baz 1980; Figure 1). The interior of Ina is characterized by various terrain types, including (1) dozens of disconnected blister-like smooth textured mounds, (2) a hummocky-textured floor unit, which is further divided into two albedo portions, light-colored and dark-colored (the latter occurs predominantly along the eastern edge of the Ina floor), and (3) bright materials found around the raised mounds and along the edges of the floor (Figure 2). On the basis of these observations and comparison with terrestrial volcanic analogues (for instance, lava pillars in northern Iceland at Dimmuborgir, Strain & El-Baz 1980), most or all of the morphologies associated with Ina were described to be volcanic in origin (El-Baz 1972, 1973; Evans & El-Baz 1973; Strain & El-Baz 1980). Specifically, the hummocky floor terrains were interpreted as solidified lava lake crust and pyroclastic deposits, and the mounds were thought to be formed as discrete lava extrusions, among the youngest volcanic features on the Moon (El-Baz 1972, 1973; Evans & El-Baz 1973; Strain & El-Baz 1980).

The international fleet of spacecraft launched to the Moon during the past decade has obtained unprecedented high-resolution imagery data for the nearly global lunar surface, especially the **Lunar Reconnaissance Orbiter** Narrow Angle Cameras (LROC NAC) onboard NASA's Lunar Reconnaissance Orbiter, which has continuously mapped the lunar surface with a pixel size of  $\sim 0.5\text{--}2\text{ m}$  (from the nominal 50 km orbit) since 2009 (Robinson et al. 2010). Survey of the LROC NAC imagery sets found many lunar surface features resembling Ina (Stooke 2012; Braden et al. 2014; Zhang et al. 2018). In particular, Braden et al. (2014) conducted a global search of NAC data and catalogued a total of 70 small mare features with Ina-like characteristics, and termed them irregular mare patches (IMPs). Integrating analyses from morphology, topography, stratigraphy, and spectroscopy of Ina and other IMP features led Braden et al. (2014) to suggest the lower hummocky terrains to be a collapsed volcanic caldera floor or fragmented lava lake crust, and the stratigraphically higher mounds to be terminal-stage lava extrusions (Figure 3). Braden et al. (2014) also investigated the size-frequency distribution of impact craters (CSFD) superposed on the mound terrains at the three largest IMPs (Ina, Sosigenes, and Cauchy 5), and found that they were all dated to be younger than 100 Ma. These ages implied significant prolongation of the lifetime of lunar volcanism from the youngest previously established  $\sim 1\text{ Ga}$  ago (e.g., Hiesinger et al. 2011; Morota et al. 2011) to geologically very recent, which, if confirmed, would raise a host of questions concerning the correctness of current models of lunar thermal and magmatic evolutions (e.g., Head & Wilson 1992; Shearer et al. 2006; Ziethe et al. 2009).

112 In addition to the geologically very recent volcanic eruption model,  
113 various alternative scenarios to account for the characteristics, age and  
114 origin of Ina/IMPs have been introduced (Table 1). These include:

115 (1) Sublimation-induced high reflectance of the floor terrains (Whitaker  
116 1972).

117 (2) Exposure of underlying ancient (>3.5 Ga) mare deposits through the  
118 removal of the surface regolith layer by sudden out-gassing of deep juvenile  
119 volatiles within the past 10 Ma (Schultz et al. 2006).

120 (3) Lava flow inflation (mounds) and subsequent lava breakout (floor  
121 hummocky terrains) (Garry et al. 2012).

122 (4) Explosive volcanic eruptions and the resultant deposition of fine-  
123 grained, block-free pyroclastics (Carter et al. 2013; note that this model is  
124 proposed for the Cauchy 5 IMP occurrence, one of the three dated young IMPs  
125 (~58 Ma; Braden et al. 2014), not specifically for Ina). A compilation of  
126 these previously-proposed scenarios and the resultant deposits for lunar IMPs  
127 can be found in Qiao et al. (2020a), and an evaluation of some of these models  
128 was presented in Qiao et al. (2018).

129 (5) Formation of Ina in the terminal stages of the associated ancient  
130 shield volcano, with the unusual characteristics and age attributed to late  
131 stage, magmatic volatile-rich lava lake activity and the resulting macro- and  
132 micro-vesicular substrate properties (Qiao et al. 2017, 2018, 2019, 2020a,  
133 2020b).

134 Following the comprehensive initial work by Braden et al. (2014), an  
135 updated catalog of the entire IMP population was compiled and comprehensive  
136 geological analyses of several representative IMPs including Ina were  
137 undertaken by Qiao et al. (2017, 2018, 2019, 2020a, 2020b). This provided more  
138 detail to this interpretation for the emplacement mechanism and age of Ina and  
139 other lunar IMPs. Qiao et al. (2020a) presented an updated inventory of 91 IMP  
140 occurrences by synthesizing previous IMP identification results. By  
141 documenting the detailed geological context information for each catalogued  
142 IMP feature, Qiao et al. (2020a) found that the modes of occurrence of the  
143 population of lunar IMPs could be classified into two major groups: (1) pit  
144 crater environment (or closed environment), in which the IMPs are contained  
145 within volcanic pits, for instance, the summit calderas of small shield  
146 volcanos, volcanic dike-tip rilles, or endogenetic pit crater chains, and (2)  
147 mare flow environment (or open environment), in which the IMPs are simply  
148 emplaced on typical basaltic mare deposits, rather than being contained within  
149 a depression (Figure 4). One of the largest IMPs, Cauchy 5 in eastern Mare  
150 Tranquillitatis, offers a unique hybrid example of the two IMP types: a large  
151 pit crater-type IMP on the shield summit vent floor and hundreds of small  
152 mare-type IMPs on the shield flanks (Qiao et al. 2020b). This hybrid IMP  
153 provides an excellent opportunity to assess the genetic relationship between  
154 the two IMP sub-types. Qiao et al. (2017, 2018, 2019) analyzed two of the

largest IMPs of pit crater-type, Ina and Sosigenes in western Mare Tranquillitatis, and proposed that the range of unusual geomorphologies and textures of the interior terrains of the largest lunar IMPs within pit craters can be explained as being due to lava lake activity involving highly vesicular/bubble-rich magma extrusion during the waning-stage evolution of a dike-tip pit crater, contemporaneously with the background mare basalts emplaced more than 3 Ga ago.

In this scenario, the hummocky and blocky floor terrains were described as a chilled lava lake crust, and the raised mounds were interpreted as final-stage extrusions of viscous magma with an extreme vesicularity, up to ~95% (magmatic foams) (Figure 4a). The unusual substrate characteristics of the final deposits, abundant macro- and micro-vesicularity for the floor terrains, and substantial micro-vesicularity for the raised mounds, were interpreted to dramatically modify the nature of post-emplacement surface modification processes, including impact cratering, regolith development and accumulation, erosion/disruption of topography, and space weathering, generating the range of highly unusual observed characteristics of Ina and leading to the anomalously young CSFD model ages reported by Braden et al. (2014). Using the hybrid geological relationships displayed at the Cauchy 5 IMP, Qiao et al. (2020b) concluded that the small mare-type IMPs were basically formed by a similar mechanism to that of the large pit crater-type IMPs, but in a different geologic settings (overflow on the rim and flank of the small mare shield volcano). In a non-shield volcano mare flow environment, the extruded highly vesicular magma foams, instead of being contained within a depression crater, would simply overflow beyond the vent rim and be emplaced on the adjacent exterior mare surface as thin foamy lava flows (lava flow Phase 4a of the eruption model of Wilson & Head 2018). Post-flow-emplacement impact events were interpreted to cause collapse in the void-rich flows, exposing the rough and coherent interiors of the foamy flows, as observed at many small mare-type IMPs (Figure 4b).

This scenario of waning-stage two-phase lava lake activity and magmatic foam extrusion is supported by a range of observations (Carter et al. 2013; Elder et al. 2017; Qiao et al. 2019, 2020b), including (1) the spatial density disparity of superposed impact craters between the interiors of IMPs (both floor and mound units) and the surrounding mare surfaces, (2) the unconsolidated substrate nature of the Ina mounds derived from Diviner thermophysical measurements, (3) the fine-grained and block-free nature of the small mare-type IMP materials from Arecibo radar mapping data (for Cauchy 5), and (4) the high reflectance and optical immaturity of the IMP deposits. The waning-stage magmatic foam eruption scenario is further supported by recent theoretical assessments of magma ascent and eruption in the final phases of activity in volcanic pit craters/vents (Wilson & Head 2017b) and lava flows (Wilson & Head 2017a, 2018; Head & Wilson 2017). These authors predicted that,

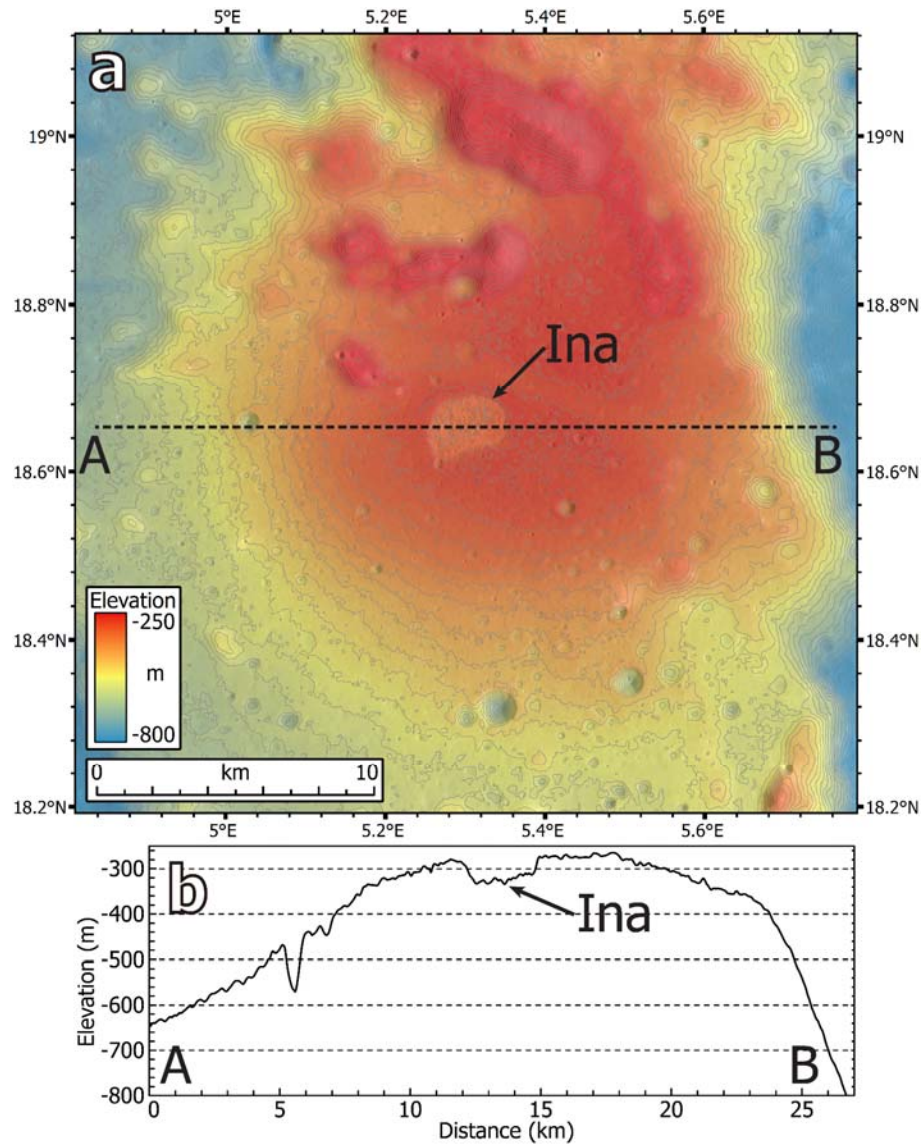

198 during the late-stage activity of lava lakes and fissure eruptions, the magma  
199 ascent rate decreased greatly, and shallow gas exsolution in the dike produced  
200 highly vesicular magmatic foams. Final-stage dike stress relaxation and dike  
201 closure would slowly squeeze the foamy magma out of the dike, cracking the  
202 partly solidified lava lake floor, and extruding the convex-upward mounds.

203 In summary, hypotheses for the origin of Ina can be subdivided into two  
204 categories (Table 1):

205 (1) Formation age: (a) Geologically extremely young, as indicated by the  
206 CSFD ages of ~33 Ma, optical immaturity, and sharp contacts; (b) Geologically  
207 ancient, coincident with the ~3.5 Ga age of the surrounding shield volcano,  
208 with other factors explained by unusual substrate characteristics; c) Hybrid,  
209 geologically old, but rejuvenated by recent activity (outgassing).

210 (2) Setting and mode of emplacement: (a) Formation in the summit pit  
211 crater of an ancient shield volcano; (b) Formation in the summit pit crater of  
212 an ancient shield volcano, but due to magmatic activity ~3.4 billion years  
213 later; (c) Formation by flow inflation processes in a summit pit crater; (d)  
214 Formation by late stage volatile exsolution processes in the waning stages of  
215 an ancient shield volcano summit vent; (e) Formation by recent deep gas  
216 release processes in an ancient shield volcano summit pit crater.

**Figure 1.** Location and general setting of Ina pit crater. (a) SLDEM2015 topography of the mare surface surrounding Ina, overlain on Kaguya TC evening mosaic, 25 m-contour interval and (b) a west-east (A-B) topographic profile across the Ina shield and summit pit crater, derived from SLDEM2015 topography.

**Figure 2.** Ina interior imagery, topographic and slope maps. (a) LROC NAC image (frame M119815703, 0.48 m/pixel,  $\sim 56^\circ$  incidence angle), (b) LROC NAC DTM topography (2 m/pixel) overlain on NAC image M119815703, (c) NAC DTM-derived slope (6 m baseline) map overlain on LROC NAC M119815703. **The solar illumination direction is indicated by the white arrow in panel a.**

**Figure 3.** Block diagram for the major structures and characteristics of Ina pit crater, and their mode of emplacement as interpreted by Braden et al. (2014), in which the uneven floor units represent fragmented lava lake crust and the mounds are interpreted to be geologically very recent lava extrusions (<100 Ma), in contrast to the surrounding very ancient mare shield deposits (~3.5 Ga) (from Head & Wilson 2017).

**Figure 4.** Models for late stage foam-rich mare basalt extrusions in (a) pit craters and (b) unconfined fissure mare foam flow environments (from Wilson & Head 2017b). (a) Magmatic processes in the dike-tip and summit vent during the final phases of a small lunar shield-building eruption (e.g., the shield underlying Ina pit crater); shallow gas exsolution to produce very vesicular magmatic foams in the dike-tip and vent floor lava lake, fracturing of the chilled and brittle lava lake crust, and squeeze-ups of the highly foamy lavas to form bulbous-shaped mounds. (b) Sequence of processes operating in a mare flow eruption from a fissure vent. Similar magmatic processes to the pit crater settings (a) are also illustrated here, but due to the lack of a confining dike-tip pit crater/vent, the highly vesicular foamy lava extrudes as a broader and thin lava flow. Post-emplacement impacts into these solidified void-rich lava flows produce many of the small-scale IMPs observed in lunar maria (Braden et al. 2014; Qiao et al. 2020a).

**Table 1**  
Theories for the Origin and Age of Ina/IMPs.

Ina/IMP origin theory	Formation age	Mode of emplacement	Reference
Sublimation	Not provided	Mounds: mare-like deposits; floor terrain: possible sublimates.	Whitaker 1972
Small lava intrusions associated with a mare dome	Among the youngest lunar volcanism, but specific age not provided	Entire Ina feature: small shield volcano; summit caldera; mounds: small volcanic eruptions.	El-Baz 1972, 1973; Strain & El-Baz 1980
Gas release-induced surface regolith removal	Surface exposure age: <10 Ma; Crystallization age: >3.5 Ga	Exposure of buried ancient mare basalts by out-gassing.	Schultz et al. 2006
Lava flow inflation	Not provided	Mounds: inflated lava flows; floor hummocky units: lava breakouts.	Garry et al. 2012
Small basaltic eruptions	<100 Ma	Mounds: small lava extrusions; floor units: lava pond crust.	Braden 2013; Braden et al. 2014

Pyroclastic eruption (proposed only for Cauchy 5 IMP, not for Ina)	Not provided	Pyroclastic deposits.	Carter et al. 2013
Lava lake processes and magmatic foam extrusion	~3.5 Ga	Floor units: solidified lava lake crust; mounds: solidified magmatic foams.	Qiao et al. 2017, 2018, 2019, 2020a, 2020b; Wilson & Head 2017b.

## 2. Significance of the Age and Origin of Ina: The Thermal Evolution of the Moon

While Ina/IMPs are now generally considered to be volcanic in origin, the specific formation mechanism is still highly controversial (Table 1). One of the most contentious issues concerning Ina's origin is its emplacement age, especially between the geologically very recent (<0.1 Ga) small basaltic eruption model (Braden et al. 2014) and the ancient (>3 Ga) magmatic foam extrusion hypothesis (Qiao et al. 2017, 2018, 2019, 2020a, 2020b; Wilson & Head 2017b). On the basis of (1) the physical volcanological study of final-stage eruption processes and volatile exsolution patterns, and (2) the detailed geological characterization of Ina's interior units, Qiao et al. (2017, 2018, 2019, 2020a, 2020b) and Wilson and Head (2017b) concluded that the interpreted magmatic foam substrate of the Ina mounds (abundant small vesicles with a bulk porosity up to ~95%) would result in superposed impact events characterized by energy partitioning that favored crushing of the void space below the projectile trajectory at the expense of lateral ejection. Thus crater diameters would be much smaller (~20-30% of the diameters of the same meteoritic impacts into typical mare regolith targets). Incorporating this "aerogel" effect of reduced impact crater diameter could readjust the observed crater retention age of less than 0.1 Ga to more than 3 Ga, coeval with the adjacent mare deposits. This ancient scenario complies with the conventional models of lunar geological and thermal evolutions, which predict that the continued net cooling of the Moon due to progressive heat loss by conduction caused mantle melting (magma source regions) to be deeper and much less abundant, and the global state of stress in the lithosphere to be increasingly contractional with time (Solomon & Head 1980; Head & Wilson 1992, 2017; Shearer et al. 2006; Ziethe et al. 2009). These factors combined to gradually inhibit the generation, ascent, and eruption of basaltic magma on the Moon, causing mare volcanic activity to diminish in middle lunar history.

(Eratosthenian Period) and eventually to cease in the last ~1 Ga (Copernican Period) (Hiesinger et al. 2011; Morota et al. 2011).

The geologically very recent small volcanic eruption origin scenario (Braden et al. 2014), however, raises a line of questions that conflicts with the above lunar evolution model, and indeed requires the overall evolution history to be very different: (1) the current lunar interior would need to be much hotter than previously thought, thus being able to maintain considerable amounts of material near the melting point, (2) the abundance of heat-producing elements (mainly Th, U, and K) in the lunar interior would have to be much higher than prior estimations, and (3) at least parts of the lunar lithosphere might be currently extensional in net state of stress, thus assisting magma in the deep lunar interior in its ascent to the surface to erupt. In addition, the IMPs are widely spread across the nearside maria and half of them are outside the Procellarum KREEP Terrane (PKT), implying that significant heat sources in many portions of the lunar interior persist to geologically very recent time in order to account for the abundant small-volume IMP eruptions. A major re-assessment of the current models of lunar thermal evolution would be required if the very young volcanic eruption origin for Ina/IMPs is verified.

### **3. Synthesis of Predictions of the Two End-Member (Young and Old) Models**

Current debate on the age and origin of Ina/IMPs centers on these two competing theories: (1) geologically very young (late Copernican) small-volume volcanic activity (Braden et al. 2014), and (2) ancient (Imbrian) volcanic eruption producing highly vesicular magmatic foams (Qiao et al. 2017, 2018, 2019, 2020a, 2020b; Wilson & Head 2017b).

#### **3.1. The Young Model**

In the late Copernican volcanism scenario (Figure 3), the uneven/hummocky floor terrains are solidified lava lake crust within the shield summit vent being disrupted by lava drainage and deflation, and the smooth mounds are subsequent small lobate lava flows extruded through the cracked floor crusts (Braden 2013; Braden et al. 2014). The mounds within Ina are 2-20 m thick (relative to the floor terrains), with an average value of 8 m, overlapping with the thickness range of mare basalt flows (e.g., Schaber 1973; Hiesinger et al. 2002). The convex-upward Ina mounds exhibit steep marginal scarps, with an average margin slope of 26° (14-39°, 6-m-baseline), another piece of evidence supporting a very young age for the Ina deposits.

Among the questions raised about the young volcanism interpretation are the following:

(1) Continued net cooling of the Moon since middle lunar history would have decreased average mantle temperature gradually, causing mantle melting to be less abundant and magma source regions to be deeper. On the basis of terrestrial analog observations (Hardee 1980), theory, and conductive cooling calculations (e.g., Wilson & Head 1981; 2017a), the lava pond in the Ina IMP could not have remained molten, following the last eruption, for more than a few hundred to a thousand years, and thus is not a source for eruptions occurring more than 3 billion years later. Bruce & Huppert (1989), Gonnermann & Taisne (2015), and Wilson & Head (1981; 1988; 2017a) also show that any magma in the dike connecting the source region to the surface would cool and solidify even more rapidly. It is also highly unlikely that the magma source region for the Ina shield volcano (at several hundred km depth) could remain molten for the 3.4 Ga long interval between the Ina shield-building eruption and any geologically very recent small magma extrusions within the 2 × 3 km summit vent; such individual source regions are typically not active for times in excess of tens to hundreds of millions of years (e.g., Wieczorek et al. 2006; Shearer et al. 2006; Marsh, 2015; Wilson & Head 2017a).

In addition, in order to extrude magma onto the surface from a molten source region located at the great depth thought to be typical of the last several hundred million years (Wieczorek et al. 2006; Shearer et al. 2006), a higher excess pressure of basaltic diapirs (hence, greater magma source volume) is required to reach the surface from such a deeper magma source region. It seems highly implausible that magma would erupt from such a great depth, and then be erupted in such small amounts (e.g., Wilson & Head 2017a; Head & Wilson 2017).

(2) The shield volcano underlying the Ina summit pit crater is apparently very ancient (e.g., Garry et al. 2012), dated to be ~3.5 Ga through crater population analysis (Qiao et al. 2017, 2019), and thus formed during the major global lunar mare volcanism phase ~3.3–3.8 Ga ago (Hiesinger et al. 2011). Conventional models of lunar thermal evolution predict that, after ~3.5–3.6 Ga ago, cooling of the outer portion of the Moon produced increasingly compressive stress in the lunar lithosphere (Solomon & Head 1980). Could magma rise from significant depths in recent thermal history of the Moon (in the last several hundred million years) along pre-existing fractures (induced by large impacts or rising diapirs)? Given the increasing overburden pressure with depth and the thicker recent lithosphere (e.g., Wieczorek et al. 2006), the closure of faults and cracks occurs at relatively shallow depths (Head & Wilson 2020b) and it is thus highly unlikely that pre-existing fractures would have remained open as pathways for rising magma for over 3 Ga. For these reasons, the required dike propagation to the surface for volcanic eruptions would be progressively more difficult with time in the period following the initial Ina shield-building eruption. These factors suggest that it is improbable that volcanic activity at the small Ina site would recur very

recently after having being dormant for ~3.4 Ga, with no evidence of at least discontinuous activity during this long period.

(3) Imaging spectroscopic analysis show that both the raised mounds and floor units within Ina have high-Ca pyroxene-dominated mineral composition similar to that of the adjacent mare deposits (Bennett et al. 2015). This is surprising, in that the young volcanism model thus predicts that the magma reservoir or source region underwent no fractional crystallization or contamination by fresh magmas in the ~3.4 Ga interval. Although Bennett et al. (2015) state that "a possible solution is that both the mare and Ina were sourced from the deep mantle, which likely would not change its composition greatly, even over such a long period of time", it seems much more likely, on the basis of the mineralogical diversity of mare basalts in individual locations with geologic time (e.g., Hiesinger et al. 2011), that the composition would not remain the same. Thus, it seems more plausible that the multiple geological units within Ina were emplaced contemporaneously with the background mare deposits ~3.5 Ga ago.

(4) The raised smooth mounds of Ina are among the most unusual terrains on the lunar surface, with a range of morphological peculiarities, including convex upward bulbous-like shapes, and marginal scarps and moats. Some young Eratosthenian lava flows in southwestern Imbrium are also observed to exhibit marginal scarps, but topographical moats are not observed at their flow margins (Schaber 1973). If these Ina mounds are normal lava flows, why is their morphology so different from that of other mare basalts? For example, the meniscus-like morphology (irregular, bleb-like shape with steep marginal slopes) is unlike any morphology identified on the Moon in typical basaltic landforms and deposits emplaced with basaltic lava rheology (Head & Wilson 2017).

(5) Diviner thermophysical mapping results for Ina indicate that the Ina interior is mantled by a surface regolith layer of measurable thickness (>10–15 cm; Elder et al. 2017). Synthesizing other thermophysical measurements including thermal inertia, Elder et al. (2017) propose some process such as explosive outgassing or pyroclastic eruptions as the origin of Ina and other lunar IMPs. Accumulation of a regolith layer of such thickness on geologically very young lava flows (~33 Ma) seems unlikely, and would require an unusually rapid development rate of lunar surface regolith (estimated to be 0.85 mm Ma<sup>-1</sup> over the last billion years by Quaide & Oberbeck 1975; a 33 Ma-old lava flow would accumulate a layer of regolith materials only ~2.8 cm thick).

(6) Basilevsky & Michael (2020, 2021) show that the morphology of young craters superposed on the Ina mounds is identical to that of craters on typical ancient mare surfaces, and interpret this to disprove the hypothesis that the mounds are formed of magmatic foams, and that this supports the relatively recent origin of the mounds. However, it has been documented (Zanetti et al. 2017; Plescia & Robinson 2019), that craters superposed on

tens of millions of years old impact melt deposits (fresh solidified bedrock) in large young craters have very different morphology from those in mature regolith. Thus, if the mounds were indeed young effusive basaltic volcanic features, we would expect small crater morphologies to be similar to those in young impact melts. Thus, the arguments of Basilevsky & Michael (2020, 2021) could be cited to support an ancient age for the mound material.

### 3.2. The Old Model

The Imbrian-age volcanic eruption model provides an alternative interpretation for the age and origin of Ina and IMPs. In this scenario, the formation of various morphological units within Ina are basically the natural consequences of the latest stage of dike emplacement and magma degassing in the summit crater atop a small lunar shield volcano ~3.5 Ga ago (Figure 4). Specifically, the floor hummocky units are interpreted as a chilled lava pond crust and the raised mounds as final-phase small magma extrusions (Qiao et al. 2017, 2018, 2019, 2020a, 2020b; Wilson & Head 2017b). In addition, waning-stage summit pit/vent activities under the unique lunar conditions of low gravitational acceleration and essentially zero-atmospheric pressure produce unusually vesicular eruption deposits neither predicted nor observed on terrestrial final-stage eruptions. Extremely porous macro-vesicular lava lake floor deposits are interpreted to favor drainage of subsequently produced regolith into the substrate and enhance the retention of optical immaturity and blockiness. Mounds are interpreted as the viscous extrusions of foamy magma that had collected below the lava lake floor in the terminal stages of the eruption. The highly vesicular substrate property of the extruded mounds is interpreted to exert notable effects on the post-emplacement impact cratering process (energy partitioning) and produced anomalously young crater retention ages ( $<0.1$  Ga).

Difficulties and critical unresolved issues also characterize the ancient, shield-contemporaneous summit lava lake magmatic foam eruption interpretation for Ina.

(1) How to convincingly explain the deficit of superposed impact craters and the resulting extremely young CSFD model ages of Ina interior deposits? Although the predicted unusually porous substrate characteristics of the Ina mounds and the consequent crater size decrease effect have been called on to account for the young crater counting ages of the Ina interior (Qiao et al. 2017, 2019; Wilson & Head 2017b), it should be noted that the consequences of impact cratering into highly porous materials and its effect on crater sizes are not yet fully understood, due to many difficulties in both laboratory impact experiments and numerical simulations. Additional dedicated theoretical, experimental and numerical studies of impact cratering into porous substrates should help to clarify the age debate on Ina and lunar IMPs,

and would also enhance our knowledge of surface processes on many porous asteroid bodies.

(2) Meteoritic impacts into the Ina foamy mounds were predicted to produce smaller and deeper ("cylinder-like" or "hole-like"), and non-blocky craters (Wilson & Head 2017b; Qiao et al. 2017). However, no such unusual craters are apparently seen on the Ina mounds (Basilevsky & Michael 2020, 2021). Instead, many impact craters superposed on the smooth mounds exhibit a range of characteristics of typical impact craters developed on mare regolith, including raised rims, ejecta deposits, blocky interiors, a range of degradations, and smaller depth-to-diameter ratios (Wagner et al. 2018; Basilevsky & Michael 2020, 2021). This appears to contradict the foam origin model for the Ina mounds. Additional work on the nature of "auto-regolith" development on extruded foamy lavas (e.g., Wilson & Head 2017b) needs to be undertaken, as well as on the nature of basaltic volcanic protoliths in general (e.g., Head & Wilson 2020a).

(3) The Ina floor terrains, especially the floor rubble materials, are characterized by unusually high reflectance and optical immaturity (Schultz et al. 2006; Garry et al. 2013; Bennett et al. 2015; Qiao et al. 2019). Any materials exposed to the harsh space environment of the lunar surface, including micrometeorite bombardment, cosmic and solar ray irradiation, and solar wind implantation, are equally subject to space weathering modification process (Pieters & Noble 2016). Over a >3 Ga period of space weathering processes, significant modification of the optical properties of the Ina floor materials should occur, resulting in surface darkening and optical maturation, possibly resembling that of the mare regolith surface surrounding the Ina pit crater. Although the conceptual model of regolith drainage into the predicted macro-vesicular void space of the lava lake floor may be plausible, a quantitative model to account for this process, the filling of the void space, the drainage-inducing processes, and the associated effects on optical maturation, has not yet been formulated. Thus, it is unknown whether the model-predicted porous substrates have significant effects on space weathering processes on the lunar surface and, if so, how these effects map out into specific observed optical alteration properties.

(4) The contacts between Ina mounds and floor terrains are typically characterized by very steep scarps and adjacent moats, some of which have the steepest topographic slopes ( $\sim 32^\circ$ ) on the Moon (Qiao et al. 2019), leading Fassett and Thompson (2015) to propose that these troughs must have been formed within the last 1–2 Ma, or perhaps are still currently forming. Any ancient model of Ina origin must also explain how to maintain the very sharp contacts at Ina over 3.5 billion years in a progressive topographic erosion environment predominantly induced by a steady impact crater flux, which serves to topographically smooth and mute such distinctive surface relief over time (Fassett & Thompson 2014). Although the moats have been attributed to

subsurface foam evacuation, loading, flexure, and regolith drainage (e.g., Wilson & Head 2017b), it is still intuitively unclear how these processes could result in such sharp and distinctive moats and contacts.

### 3.3. Summary

We thus conclude that in order to resolve the differences between these two hypotheses for the origin of Ina, new data, experiments, and missions are required. In the following sections we first identify the key **observations and** measurements that would help distinguish between the two models, and then define a range of mission types that could be undertaken to provide these data. For simplicity, we refer to the Braden et al. (2014) hypothesis (Figure 3) as the Ina-is-younger model (**Young-model**), and the Qiao et al. (2017, 2019) shield-contemporaneous ~3.5 Ga model as the Ina-is-older model (**Old-model**).

## 4. Key Observations and Measurements to Distinguish between the End-member Models

In this section, we list a sequence of key observations and measurements from the Ina surface and on samples that would help explain the range of enigmatic features in Ina and resolve key questions concerning the origin of Ina, especially the “age question”: What is the age of the units comprising the Ina IMP (mounds and floor unit)? Concurrent with the emplacement of the small shield volcano and surrounding mare deposits, and thus over three billion years old? Formed in the last few tens of millions of years, as interpreted from superposed impact crater size-frequency distributions?; and the “mode of origin of the units question”: What is the origin of the units comprising the Ina IMP (mounds and floor unit)? Minor variations on typical lunar mare basalt lava flow emplacement processes? Major variations in the vesicularity and physical properties of basaltic magmas intruded in the terminal phases of shield volcano summit pit crater eruptions? In particular, these observations and measurements would help distinguish between the two end-member models: Young-model (Braden et al. 2014) and Old-model (Qiao et al. 2017, 2019).

(1) Radiometric ages of the Ina mounds and floor materials: Acquisition and radiometric dating of samples of the material that makes up the mounds and floor units would provide unequivocal evidence to distinguish between the two models. **These measurements are necessary and sufficient to unambiguously resolve the key question concerning the formation age of Ina deposits.** The magnitude of the age difference between the two models (>3.4 Ga or a factor of over 100) is so large that perhaps even in-situ age determination (e.g., Anderson et al. 2017) could resolve the controversy.

(2) Characteristics of the regolith material on the mounds and on the floor: Predictions of the **Young-model** suggest that the regolith is derived

from recently emplaced basalts and thus the regolith development from this protolith (Head & Wilson 2020a) should be standard impact fragmentation of solid basalt to produce a regolith. The **Old-model**, on the other hand, predicts that the mound protolith will be very vesicular magmatic foam, with an "autoregolith" of explosively fragmented bubble wall shards and an impact-induced regolith produced from, and on top of, this substrate. The floor unit is predicted to be composed of macro-vesicular basalt with regolith draining into the void spaces, leaving larger and optically immature particles and rocks on the surface. Thus, there should be a clear distinction possible between the two models on the basis of the predicted substrate characteristics. In-situ observations (high-resolution images of regolith particles in both terrains to assess their grain size, shape, optical maturity, agglutinates, proportion of glass, etc.), sieves to assess particle size distributions, and observations to assess the nature of the moats and search for evidence of macro-vesicular voids and associated regolith drainage in the floor units and subunits. **In addition, detailed Ina regolith property analyses would also help test or verify other formation theories of Ina (Table 1). For instance, if typical normal mare regolith characteristic is observed, it is also consistent with the recent gas released-induced removal of ancient regolith model (Schultz et al. 2006).**

(3) 3-D structure of the mounds and floor material (porosity): Emplacing core tubes in the upper meters of the floor and mound regolith deposits would be a significant step in documenting the vertical structure, variability and origin of the regolith. A much more comprehensive view could be obtained by ground penetrating radar (GPR) surveying (e.g., Xiao et al. 2015; Lai et al. 2019; Li et al. 2020) of the mound and floor units. Seismic profiling could also determine the nature of the mound and floor unit three-dimensional structure, and readily distinguish between the normal basaltic substrate of the **Young-model** and the highly macro- and micro-vesicular nature of the **Old-model**.

(4) Regolith thickness; any change with depth on mound and floor material: Comparison of regolith thickness (and nature) through coring, GPR and seismic studies will also be critical in distinguishing between the **Old-model** (thicker and more mature regolith developed over >3.4 Ga) and **Young-model** (much thinner and patchy regolith developed over ~33 Ma).

(5) Nature of ejecta from craters into mound and floor material: Assessment of the morphology and frequency distribution of superposed impact craters of different sizes will help in identifying any distribution that might deviate from standard basaltic morphologies and proportions, or alternatively that might signal the presence of a substrate or regolith of foamy or marco-vesicular nature. Analysis and sampling of crater ejecta from different sized craters will also reveal changes in the substrate with depth that will distinguish between the **Old- and Young-model** predictions.

(6) Level of vesicularity of surface rocks: Surface observations and analysis of crater ejecta indicating subsurface layers, and their level of vesicularity will also help to distinguish between the two hypotheses, with **Old-model** predictions requiring very significant macro-vesicularity in the floor units, and magmatic foam-level vesicularity in the mound unit.

(7) Volatile content of magma petrogenesis: Return of samples to Earth for laboratory analysis and petrogenetic probing will provide essential data to identify depth of origin of magmas, petrogenetic pathways, and the nature and amount of volatiles necessary to produce magmatic foams.

(8) Comparison of rocks, soils (and ages) inside Ina and on the shield rim: An extended traverse to the Ina shield volcano rim and flanks, the collection of samples there to compare with those collected on the floor of Ina, and analysis of comparative ages, vesicularities and petrogenesis would provide conclusive evidence to distinguish between the **Old- and Young- models** for the origin of Ina.

(9) Paleomagnetism measurements: In-situ magnetic analyses, or laboratory analysis of returned samples, would provide important evidence to distinguish between the two hypotheses. Magnetized samples would support the **Old-hypothesis** as the lunar magnetic field is interpreted to have been active at ~3.5 Ga, but to have decayed by the time (~33 Ma) derived from CSFD ages (Weiss & Tikoo 2014).

## 5. Missions Capable of Addressing these Objectives

In this section we present an assessment of several mission styles and modes, optimal landing sites, and where appropriate, conceptual traverses. We conclude with a human landing and exploration design reference mission (DRM).

(1) Robotic lander Mission (with or without hopping mobility): A single robotic lander mission with no mobility (e.g., Stopar et al. 2019) could significantly contribute to distinguishing between the two hypotheses by carrying a payload consisting of a high-resolution multispectral imager, a microscopic imager for grain size and morphology, a magnetometer, a scoop to dig into the subsurface and assess the mechanical properties of the regolith, an in-situ GPR as manifested on the Chang'e-5 lunar lander (Li et al. 2019b; Xiao et al. 2019), and, if possible, an in-situ geochronology instrument to clarify the age debate of Ina deposits (e.g., a K-Ar laser experiment developed by Cohen et al. 2014). If limited to a single mission, the spacecraft should land on a mound on the floor of Ina (e.g., Stopar et al. 2019 and Figure 5), as the mound characteristics (basaltic regolith versus magmatic foam regolith and auto-regolith) are the most prominent predictions to distinguish between the two models **and test other formation theories of Ina (Table 1)**.

Hopping capability would significantly assist in assuring representative measurements and determining diversity within the mound, and long hops or

multiple hops might permit access to the floor units as well. Multiple landing missions would also accomplish these goals.

(2) Robotic Sample Return Mission: The most conclusive results to distinguish between the models would result from a sample return mission. A robotic probe, similar to the Chang'e-5 sample return mission profile (Li et al. 2019a), to a mound landing site would be ideal (e.g., Figure 5), with imaging systems to document the local setting, GPR to probe the subsurface regolith and bedrock structure, a scoop to assess the upper parts of the regolith and collect samples, and a meters-scale core to sample with depth. Returned to Earth, these samples could be fully assessed from a geologic, chronologic, geophysical, and petrogenetic perspective and a clear and concise answer could be obtained.

(3) Robotic Rover Mission: Addition of mobility to a lander mission would significantly enhance the science return and not only distinguish among the hypotheses, but also help to understand the actual array of processes involved in the formation of the Ina structure (and similar features such as Sosigenes, Cauchy 5, and the population of smaller IMPs (Braden et al. 2014; Qiao et al. 2020a)). For example, rovers could traverse from a landing on the relatively smoother mounds to the mound flanks, the various units on the Ina floor, and perhaps even to the rim of the pit crater to compare and contrast the characteristics of the Ina floor with those of the shield volcano itself (Figure 6). Traverse geology (imaging and trafficability), geophysics (magnetic, seismic, and GPR traverses), detailed sample analyses (multispectral mineralogy and microscopic imaging), as well as the ability to probe the upper meters of regolith (scoops and rover tracks) are also essential.

(4) Human Landing and Exploration Mission: With a resurgence of interest in lunar exploration, including China's continued Lunar Exploration Program (CLEP), the NASA program of "Forward to the Moon with Artemis," and the parallel and cooperative human exploration endeavors of ESA, Russia, India, and others, human exploration of the Moon is clearly feasible in the first half of the 21st century. Here we present a design reference mission for an Apollo J-Mission-scale expedition to the Ina summit pit crater and vicinity (Figure 7), designed specifically to resolve the issue of the two (old and young) origins for the Ina crater interior, but more importantly to provide the data to establish a refined or new model that can help explain these enigmatic features in Ina, as well as other large features such as Sosigenes and Cauchy 5, and the many dozens of smaller IMPs in the lunar maria (e.g., Braden et al. 2014; Qiao et al. 2020a).

In this "Design Reference Mission" (Figure 7), we propose landing on the floor of Ina on the largest of the mounds (formally named Mons Agnes, Figure 7) and deploying ALSEP (Apollo Lunar Surface Experiments Package)-like geophysical monitoring stations, and undertaking extensive coring and analysis

of the regolith and substrate of the mounds, sampling laterally within walking distance with meters-scale cores and extensive geologic observations and sampling, guided by Astronaut visual observations and in-situ GPR data. Following the first EVA (extravehicular activity; yellow path in Figure 7), the crew would traverse due east, down the flanks of the mound, across the moat (labelled in Figure 7), stopping to examine the characteristics and morphology of the moat structure, before proceeding across the more mature floor regolith deposits. Samples and observations here from traverse geophysics and GPR data will help measure the substrate density and search for evidence of macro-vesicularity predicted by the **Old-model**. The second traverse (gold path in Figure 7) continues to the bright and optically immature blocky unit and outcrops at the eastern margin of the Ina floor (labelled in Figure 7), where stratigraphy may also be exposed in the marginal scarp. Following analysis of the floor margin contact, the traverse would continue up the wall of the pit crater to the rim to continue traverse geophysics and sampling to compare the ancient rim of the shield volcano with the potentially >3 Ga younger floor (Figure 7). The traverse would then extend along the southeast rim of the pit crater, obtaining perspective views and measurements of the Ina interior, and then descend down to the pit crater floor at the "vermicular" terrain, before heading to the western margin of the largest Ina mound and moat, and ascending the mound back to the landing site (Figure 7). Total traverse distance of the first EVA would be about 3.2 km, a modest distance compared with Apollo J-Mission traverses. The second EVA (traverse 3 shown as the blue path in Figure 7) would traverse from the landing site in a west-southwest direction, crossing multiple mounds for comparison with the major mound, its moat margins and the intervening floor subunits, and would have as a target, an unusual blocky impact crater on the southwest Ina floor (Ivanov & Head 2019, labelled in Figure 7). Here, exploration and analysis of the unusual nature of impact craters and the stratigraphic relationships between mounds and floor units will significantly assist in the determination of the origin of the Ina floor deposits and the specific processes operating to form them. A fourth traverse (cyan path in Figure 7) explores the northern and northwestern part of the Ina floor, providing additional characterization of the Ina floor units and their three-dimensional structure. The astronauts would traverse down onto a peculiar "low" mound feature (labelled in Figure 7) in the northern floor. This "low" mound is ~100×80 m in size, the largest one among six "low" mounds identified in Ina interior floor with smooth surface textures and lower elevations than the surrounding terrains (Qiao et al. 2019). These extensive geologic field investigations and sampling of Ina's materials will provide fundamental insights into its characteristics and formation mechanisms. Together, these four traverses cover a total distance of about 11.6 km (Figure 7), well within the range for the successful Apollo J-missions (~28–36 km in Apollo 15, 16, and 17). Clearly, human exploration and

associated mobility provide significantly more scientific results than can be obtained by a robotic mission alone.

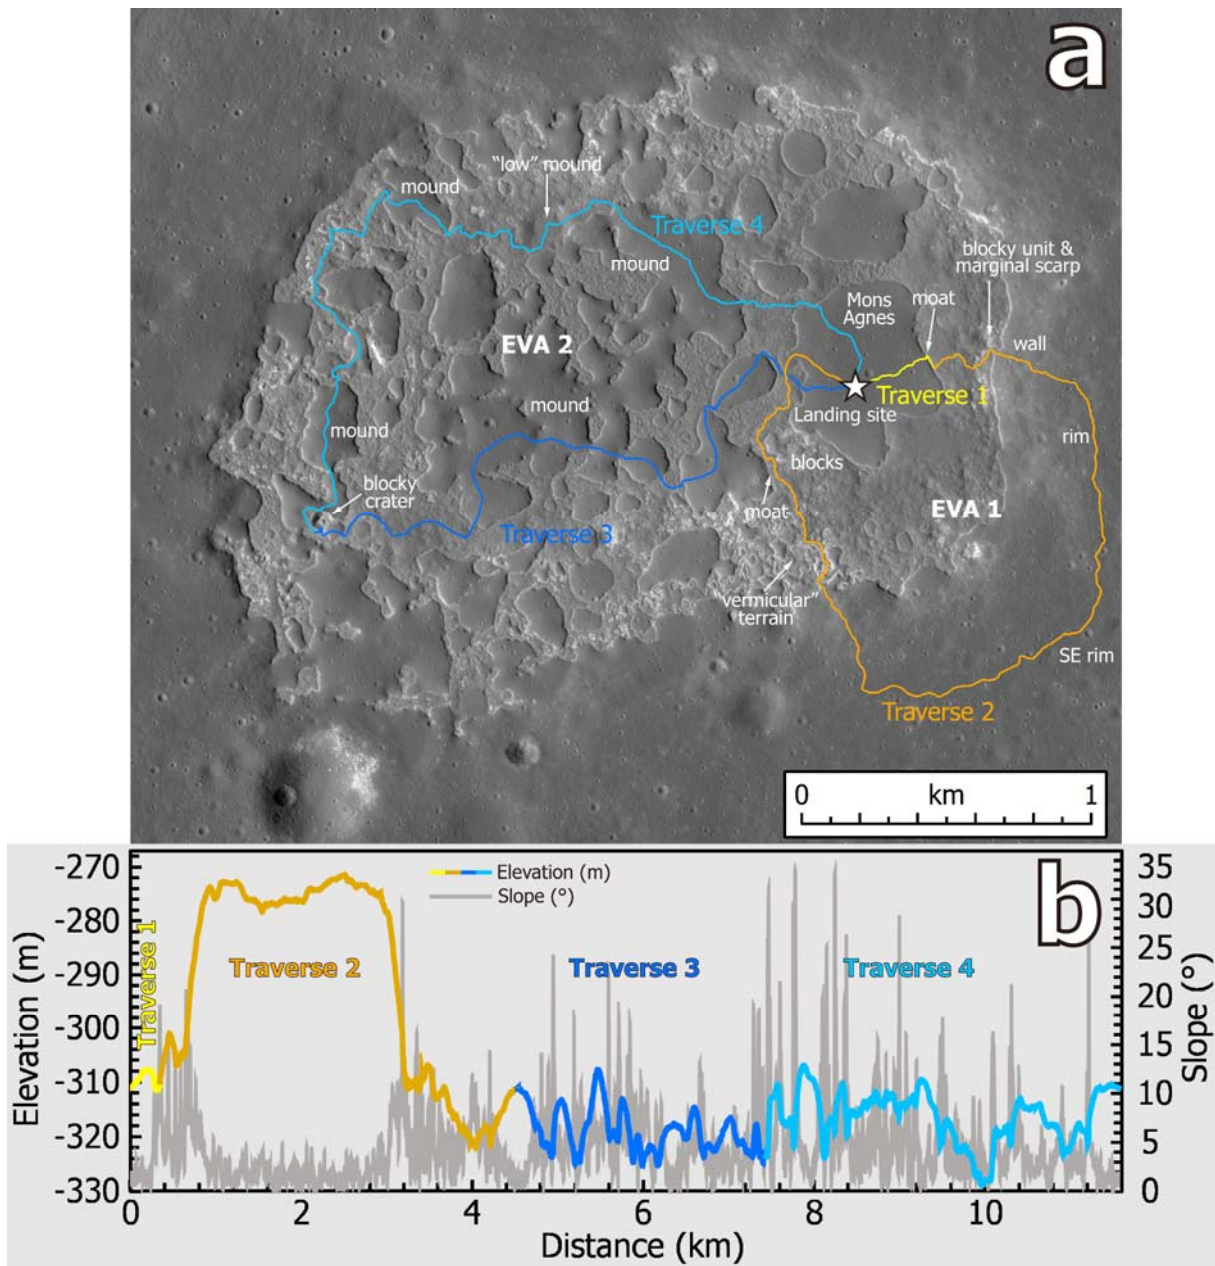

However, the nature of slopes and the physical structure of regolith along the proposed traverses (Figures 6 and 7) may present some challenges to human and robotic exploration. For example, the slopes at the margins of mounds in our traverse may sometimes exceed those encountered by Lunokhod and Apollo rovers (Basilevsky et al. 2019) and thus engineering designs and operational strategies need to take this into consideration. In addition, the macro-porosity and regolith characteristics predicted by some models (e.g., magmatic foam mounds and macro-porous floor; Qiao et al. 2017, 2019; Wilson & Head 2017b) may introduce potential trafficability and soil particle contamination problems that should be taken into consideration during mission planning (e.g., including ground penetrating radar instruments; design to accommodate very fine angular particles).

**Figure 5.** LROC NAC images of mound terrains (all cropped from frame M119815703) proposed as landing targets for robotic lander and/or sample return missions.

**Figure 6.** (a) Proposed landing site (marked by the black cross hair) and traverse path for a robotic rover mission to the Ina pit crater; surface investigation sites are labelled. The background is cropped from LROC NAC frame M119815703. (b) LROC NAC DTM elevation (black line) and slope (grey line) profiles along the traverse path.

**Figure 7. (a)** Traverse map of our proposed human landing and exploration “Design Reference Mission” to the Ina pit crater and vicinity, showing the suggested landing site (star symbol) on the largest mound (Mons Agnes), astronaut traverse paths during the first (including traverse 1 and 2) and second (including traverse 3 and 4) extravehicular activities (EVA), and scientific investigations sites (labelled by terrain names). The background is cropped from LROC NAC frame M119815703. **(b)** LROC NAC DTM elevation (color line) and slope (grey line) profiles along the traverse paths.

## 6. Conclusions

The Ina pit crater is one of the most mysterious lunar features identified and investigated during the Apollo era (Whitaker 1972; El-Baz 1973). Its range of geological peculiarities has perplexed lunar scientists for decades and resulted in a wide variety of hypotheses for their origins. Ina is also the most notable representative of a group of dozens of small mare features, identified on high-resolution LROC NAC images and termed Irregular Mare Patches (IMPs; Stooke 2012; Braden et al. 2014). However, the specific formation mechanism and emplacement age of Ina and other lunar IMPs have been long debated, and various competing theories have been proposed to account for the characteristics, age, and origin of Ina/IMPs (Table 1). One of the most contentious issues concerning Ina's origin is the actual emplacement age, especially the disparity between the geologically very young ( $<0.1$  Ga) small volcanic eruption model (**Young-model**; Braden et al. 2014) and the very old ( $>3$  Ga) magmatic foam extrusion hypothesis (**Old-model**; Qiao et al. 2017, 2018, 2019, 2020a, 2020b; Wilson & Head 2017b). Distinguishing between the two competing theories will provide vital constraints on the cessation time of lunar mare volcanism, either the previously established  $\sim 1$  Ga ago (Hiesinger et al. 2011; Morota et al. 2011) or the recently proposed geologically very recent  $\sim 18$  Ma (Braden et al. 2014); this is a key parameter for modeling the geological and thermal evolution of the Moon.

We conclude that in order to resolve the controversy between these two very different scenarios for the origin and age of Ina, new data, experiments, and sample returns from new landed lunar missions are required. **To unequivocally resolve the question of the ancient or recent age of the Ina irregular mare patch, a robotic sample return mission, such as the recent Chang'e-5 mission (Li et al. 2019a), is required. In order to unequivocally resolve the question of the origin of the geologic units comprising the Ina IMP, a robotic rover or human exploration mission that can traverse and examine the soils, rocks and substructure of the units is required.** In this contribution, we identify key measurements from the Ina surface and on samples that would help distinguish between the two end-member models, including radiometric ages of Ina deposits, the nature of regolith materials, 3-D shallow subsurface structure, volatiles involved in magma petrogenesis, and paleomagnetism. In the current international circumstances of a resurgence of lunar exploration endeavors, we define a range of conceptual lunar missions to the Ina feature, including mission styles, optimal landing sites, and conceptual traverses for robotic lander and/or rover missions, robotic sample return missions, and human landings and exploration. These missions will provide vital data not only to resolve the issue of the two (old and young) origins for the Ina crater interior, but also more importantly to establish a refined or new model that can help explain these enigmatic features in Ina, as well as other large features such as Sosigenes and Cauchy 5, and the many

dozens of smaller IMPs in the lunar maria (e.g., Braden et al, 2014; Qiao et al., 2020a).
